RL-Based Dynamic Pricing Simulator

Architectural Design, Mathematical Formulation, and Implementation Report

Pricing Research

March 2026

Abstract

This report presents a comprehensive simulator for training reinforcement learning (RL) policies on dynamic markdown pricing in a retail environment. The system models a catalog of 15 products across 5 categories over a 91-day (13-week) markdown period encompassing major retail events including Black Friday, Christmas, and New Year. It incorporates customer choice models with demographic segmentation, self- and cross-price elasticity, a promotional attention mechanism that amplifies demand for discounted items, a seasonal event calendar with demand multipliers, weekly sticky pricing decisions, inventory depletion, and financial accounting. The simulator exposes a Gymnasium-compatible Markov Decision Process (MDP) interface with discrete action tiers and action masking, and generates synthetic CSV datasets for offline pre-training. We train a Soft Actor-Critic (SAC) agent, comparing against zero-discount, random, and heuristic baselines. SAC achieves a 29% margin improvement over the heuristic while using 63% less discount budget, clearing 99.9% of inventory. The promotional attention mechanism ensures that discounting creates genuine demand lift beyond mere affordability effects, and the holiday calendar introduces non-stationary demand that the agent must anticipate and exploit. We detail the mathematical formulation, software architecture, training methodology, and results.

13 Conclusion **17**

1 Introduction

Dynamic markdown pricing—the strategic reduction of prices to clear seasonal or perishable inventory within a fixed time window—represents a fundamental operations research problem in retail. Traditional rule-based approaches (e.g., "apply 20% off after week 2") fail to capture the complex interactions between product substitutability, customer heterogeneity, and budget constraints.

Reinforcement learning offers a principled framework for discovering optimal pricing policies through interaction with an environment. However, training RL agents in live retail settings is impractical due to revenue risk. A high-fidelity simulator is therefore essential.

This report describes the design, mathematical formulation, and implementation of such a simulator. The system serves two purposes:

(i) **Offline data generation**: Producing realistic historical datasets under heuristic policies for batch RL or supervised pre-training.

(ii) **Online environment**: Providing a step-by-step MDP interface (compatible with Gymnasium) for policy gradient or value-based RL algorithms.

2 System Architecture

The simulator is organized as a Python package with the following modules:

Table 1: Module architecture overview.

Module	Responsibility
`config.py`	Product catalog definition, elasticity parameters, MDP hyperparameters, discount action tiers, and seasonal event calendar.
`customer.py`	Customer arrival model (Poisson process), demographic segmentation, willingness-to-pay (WTP) generation, and purchase decision logic.
`demand.py`	Demand orchestration combining self-elasticity multipliers, cross-elasticity adjustments, and the customer choice model.
`engine.py`	Core simulation engine: executes one-step transitions, tracks inventory, and computes financials.
`environment.py`	Gymnasium `Env` subclass exposing the MDP interface with observation construction, action masking, and reward computation.
`data_generator.py`	Runs full episodes under heuristic or random policies and exports CSV datasets.

The call hierarchy for a single time step proceeds as:

`MarkdownPricingEnv.step()` $\longrightarrow$ `RetailSimulator.step()` $\longrightarrow$ `DemandEngine.simulate_day()` $\longrightarrow$ `Cus`

3 Hidden Environment Dynamics

The internal dynamics model the ground truth of retail demand. These mechanics are *not* exposed to the RL agent—it only observes aggregate state vectors.

3.1 Customer Choice Model

3.1.1 Arrival Process

Customer arrivals on day t follow a Poisson process:

$$N_t \sim \text{Poisson}\big(\lambda \cdot m_{w(t)}\big), \tag{1}$$

where $\lambda = 80$ is the base daily arrival rate and $m_{w(t)}$ is a day-of-week multiplier:

Table 2: Day-of-week arrival multipliers.

Day	Mon	Tue	Wed	Thu	Fri	Sat	Sun
m_w	0.80	0.85	0.90	1.00	1.15	1.30	1.20

3.1.2 Demographic Segmentation

Each customer is assigned to one of $K = 3$ segments with probabilities $\boldsymbol{\pi} = (0.40, 0.40, 0.20)$:

Table 3: Customer segments and WTP multipliers.

Segment	**Proportion**	**WTP Multiplier** α_k
Budget	40%	0.70
Mainstream	40%	1.00
Premium	20%	1.35

3.1.3 Willingness to Pay

For a customer in segment k, the WTP for product p with base price b_p is drawn from a log-normal distribution:

$$\text{WTP}_{k,p} \sim \text{LogNormal}\big(\ln(\alpha_k \cdot b_p),\ \sigma\big), \qquad \sigma = 0.15. \tag{2}$$

This ensures WTP is strictly positive and exhibits right-skewed heterogeneity within each segment.

3.1.4 Purchase Decision

A customer buys at most one unit of one product. The decision rule:

1. Identify the set of *affordable* products: $\mathcal{C} = \{p : \text{WTP}_p \geq \tilde{b}_p \text{ and } i_p > 0\}$, where $\tilde{b}_p = b_p(1 - d_p)$ is the shelf price under discount d_p.
2. If $\mathcal{C} = \emptyset$, the customer leaves without purchasing.
3. Otherwise, select product p^* with probability proportional to consumer surplus:

$$\Pr(p^* = p \mid \mathcal{C}) = \frac{\max\big(\text{WTP}_p - \tilde{b}_p,\ 0\big) \cdot w_p}{\sum_{j \in \mathcal{C}} \max\big(\text{WTP}_j - \tilde{b}_j,\ 0\big) \cdot w_j}, \tag{3}$$

where w_p is the promotional attention weight defined below.

3.1.5 Promotional Attention Mechanism

Discounts attract customer attention beyond their pure affordability effect. A promoted product receives additional weight in the selection probability through an attention multiplier:

$$w_p = 1 + \phi \cdot d_p, \tag{4}$$

where $\phi = 3.0$ is the promotional lift factor and d_p is the discount fraction. At a 30% discount, $w_p = 1.9$, nearly doubling the product's selection probability relative to an undiscounted product with the same surplus. This captures the empirical observation that promoted items receive disproportionate attention through shelf signage, price tags, and end-cap displays.

Verification with synthetic customers shows a 10.6× demand lift for a 30% discounted product, with mild cannibalization of substitutes (-1.1 units for same-category products) and a net 26% increase in total units sold across the catalog.

3.2 Demand and Elasticity Engine

3.2.1 Self-Elasticity (Log-Log Model)

The discount applied to product p modulates its demand through a constant-elasticity model. The arrival rate multiplier for the store is:

$$\mu(\mathbf{d}_t) = \frac{1}{P} \sum_{p=1}^{P} (1 - d_{t,p})^{\varepsilon}, \tag{5}$$

where $\varepsilon = -2.0$ is the self-elasticity exponent and P is the number of products. The effective number of arrivals becomes $N'_t = N_t \cdot \mu(\mathbf{d}_t)$.

Since $\varepsilon < 0$, a price reduction (increasing d_p) leads to a demand multiplier greater than 1, capturing the standard economic relationship between price decreases and demand increases.

3.2.2 Cross-Elasticity Matrix

Let $\mathbf{E} \in \mathbb{R}^{P \times P}$ denote the cross-elasticity matrix with $E_{pp} = 0$ (diagonal). The demand adjustment for product i given discount vector $\mathbf{d}$ is:

$$\Delta q_i = -\sum_{j=1}^{P} E_{ij} \cdot d_j \cdot q_i^{\text{base}}, \tag{6}$$

where q_i^{base} is the demand from the customer choice model before cross-effects.

The sign convention:

- $E_{ij} > 0$ (substitutes): discounting product j *cannibalizes* product i. Example: discounting Greek Yogurt reduces Cheddar Cheese sales.
- $E_{ij} < 0$ (complements): discounting product j *boosts* product i. Example: discounting Sourdough Bread increases Cheddar Cheese sales.

In our catalog, same-category products are substitutes ($E_{ij} = 0.15$), while dairy–bakery and snacks–beverages pairs are complements ($E_{ij} = -0.075$).

3.3 Inventory and Fulfillment

Inventory for each product is tracked as a non-negative integer:

$$i_{t+1,p} = i_{t,p} - q_{t,p}, \qquad q_{t,p} \leq i_{t,p}. \tag{7}$$

When $i_{t,p} = 0$:

- The product is excluded from customer choice sets (lost demand).
- Discounting is automatically masked to $d_{t,p} = 0$.

3.4 Seasonal Event Calendar

The simulator models a 91-day markdown horizon (13 weeks) aligned with the peak retail season (late November through February). A calendar of seasonal events creates non-stationary demand patterns that the RL agent must learn to anticipate and exploit:

Table 4: Seasonal event calendar with demand multipliers.

Event	**Days**	**Duration**	**Demand Multiplier**
Black Friday	0–1	2 days	2.5×
Thanksgiving Weekend	2–4	3 days	1.8×
Cyber Week	5–11	7 days	1.4×
Pre-Christmas Rush	42–55	14 days	1.5×
Christmas Eve	54	1 day	2.0×
Boxing Day Sales	56–58	3 days	1.8×
New Year's Eve	61	1 day	1.6×
January Clearance	70–90	21 days	0.7×

The event multiplier e_t is applied to the Poisson arrival rate:

$$N_t \sim \text{Poisson}\big(\lambda \cdot m_{w(t)} \cdot e_t\big). \tag{8}$$

When events overlap (e.g., Christmas Eve during Pre-Christmas Rush), the maximum multiplier is used. The January Clearance period ($e_t = 0.7$) models post-holiday demand decline, creating urgency to clear remaining inventory before the markdown period ends.

3.5 Financial Mechanics

For each product p at time t:

$$\text{Shelf price:} \quad \tilde{b}_p = b_p(1 - d_p), \tag{9}$$

$$\text{Revenue:} \quad R_{t,p} = \tilde{b}_p \cdot q_{t,p}, \tag{10}$$

$$\text{COGS:} \quad C_{t,p} = c_p \cdot q_{t,p}, \tag{11}$$

$$\text{Margin:} \quad M_{t,p} = R_{t,p} - C_{t,p}, \tag{12}$$

$$\text{Discount cost:} \quad \Delta_{t,p} = (b_p - \tilde{b}_p) \cdot q_{t,p} = b_p \cdot d_p \cdot q_{t,p}. \tag{13}$$

Total daily discount cost is $\Delta_t = \sum_p \Delta_{t,p}$, which depletes the markdown budget.

4 Synthetic Data Generation

The data generator runs the simulator under a baseline policy (heuristic or random) to produce three CSV files for offline analysis and pre-training.

4.1 Product Metadata

Table 5: Schema for `product_metadata.csv`.

Column	Type	Description
`product_id`	int	Unique identifier (0-indexed).
`name`	str	Human-readable product name.
`category`	str	Product category (dairy, bakery, protein, beverages, snacks).
`base_price`	float	Regular (undiscounted) price in dollars.
`unit_cost`	float	Cost of goods sold per unit.
`initial_inventory`	int	Starting inventory count for the markdown period.

4.2 Daily State Transitions

Each row of `daily_state_transitions.csv` records the full (s_t, a_t, r_t, s_{t+1}) tuple:

Table 6: Key columns in `daily_state_transitions.csv` (83 total columns for 15 products).

Column Pattern	Description
`day`, `day_of_week`	Time indices.
`discount_p{i}`	Discount fraction applied to product i.
`units_sold_p{i}`	Units sold for product i.
`inventory_p{i}`	Post-step inventory for product i.
`revenue_p{i}`	Revenue from product i.
`discount_cost_p{i}`	Discount expenditure for product i.
`total_revenue`	Sum of all product revenues.
`total_margin`	Sum of all product margins.
`total_discount_cost`	Sum of all discount costs.
`budget_remaining`	Remaining markdown budget after this step.
`time_remaining`	Days remaining in the markdown period.
`reward`	Scalar reward for the transition.

4.3 Transaction Log

Table 7: Schema for `transaction_log.csv`.

Column	Type	Description
`day`	int	Day on which the transaction occurred.
`product_id`	int	Purchased product ID.
`product_name`	str	Purchased product name.
`segment`	str	Customer demographic segment.
`wtp`	float	Customer's realized willingness to pay.
`price_paid`	float	Shelf price at point of sale.
`surplus`	float	Consumer surplus (WTP − price paid).
`discount_applied`	float	Discount fraction in effect for the product.

4.4 Baseline Policies

Two policies are implemented for data generation:

Random Policy. Each product's discount tier is drawn uniformly at random from A_{allowed} at each time step.

Heuristic Policy. A time-and-inventory-pressure rule:

$$\text{pressure}_p = 0.5 \cdot \frac{t}{H} + 0.5 \cdot \frac{i_{t,p}}{i_{0,p}}, \tag{14}$$

where H is the markdown horizon and $i_{0,p}$ is the initial inventory. The pressure index is mapped to a discount tier, with a budget guard to prevent overspending.

5 MDP Formulation

5.1 State Space

At each time step t, the agent observes a composite state vector:

$$\boxed{S_t = \left[\, \mathbf{d}_{t-1},\ \ \mathbf{q}_{t-1},\ \ \mathbf{i}_t,\ \ \mathbf{c}_{t,\text{cumul}},\ \ B_t,\ \ T_t,\ \ W_t,\ \ E_t \,\right]} \tag{15}$$

Table 8: State vector components (total dimensionality: $4P + 10$ where $P = 15$, giving 70).

Component	Dim	Description
$\mathbf{d}_{t-1}$	P	Previous discount vector (raw fractions).
$\mathbf{q}_{t-1}$	P	Previous demand vector (normalized by initial inventory).
$\mathbf{i}_t$	P	Current inventory (normalized by initial inventory).
$\mathbf{c}_{t,\text{cumul}}$	P	Cumulative discount cost per product (normalized by total budget).
B_t	1	Remaining budget fraction $\in [0, 1]$.
T_t	1	Time remaining fraction $\in [0, 1]$.
W_t	7	Day-of-week one-hot encoding.
E_t	1	Seasonal event multiplier (normalized by max event multiplier 2.5).

All continuous components are normalized to approximately $[0, 1]$ to facilitate neural network training.

5.2 Action Space and Masking

5.2.1 Discrete Discount Tiers

The action space is a multi-discrete space:

$$\mathbf{a}_t \in \prod_{p=1}^{P} A_{\text{allowed}}, \qquad A_{\text{allowed}} = \{0.0,\ 0.10,\ 0.20,\ 0.30,\ 0.50\}. \tag{16}$$

Each product independently selects from $|A_{\text{allowed}}| = 5$ discount tiers. The total action space has $5^{15} \approx 3 \times 10^{10}$ combinations.

Using discrete tiers rather than continuous actions:

- Ensures **sample efficiency** by reducing the action space from $\mathbb{R}^{15}$ to a finite combinatorial set.

- Matches real retail practice where discounts are applied in fixed increments.
- Enables algorithms like PPO with multi-discrete action heads or DQN with action decomposition.

5.2.2 Action Masking

For any product p with zero inventory ($i_{t,p} = 0$), the action is forced to tier index 0 (no discount):

$$a_{t,p} = 0 \quad \text{if } i_{t,p} = 0. \tag{17}$$

The mask tensor $\mathbf{M}_t \in \{0,1\}^{P \times |A|}$ is provided in the `info` dictionary:

$$M_{t,p,k} = \begin{cases} 1 & \text{if } i_{t,p} > 0 \text{ or } k = 0, \\ 0 & \text{otherwise.} \end{cases} \tag{18}$$

Policy networks must apply this mask before sampling (e.g., setting logits of invalid actions to $-\infty$).

5.3 Weekly Decision Frequency (Sticky Pricing)

In real retail, prices are typically set on a weekly cadence rather than daily. The simulator implements *sticky pricing* with a configurable decision frequency $f = 7$ days. Each MDP step corresponds to one pricing decision that is held fixed for f consecutive simulation days:

$$d_{t,p} = d_{\tau,p} \quad \text{for } t = \tau f, \tau f + 1, \ldots, \tau f + f - 1, \tag{19}$$

where τ is the MDP step index.

With a 91-day horizon and $f = 7$, the agent makes $\lceil 91/7 \rceil = 13$ pricing decisions per episode. The reward for each MDP step is the *sum* of daily rewards over the f-day window:

$$R_\tau = \sum_{t=\tau f}^{\tau f + f - 1} r_t, \tag{20}$$

where r_t is the daily reward from Equation (21).

This design ensures:

- **Realism**: Matches real retail pricing cadence where weekly circulars and price labels are updated once per week.
- **Tractable training**: Reduces the effective horizon from 91 steps to 13, improving credit assignment.
- **Strategic depth**: Each decision has a week-long consequence, requiring the agent to anticipate multi-day demand patterns including weekend surges and holiday events.

5.4 Transition Dynamics

Given action $\mathbf{a}_t$ (decoded to discount vector $\mathbf{d}_t$), the transition proceeds:

Algorithm 1 Single-step transition dynamics

Require: Discount vector $\mathbf{d}_t$, current inventory $\mathbf{i}_t$, budget B_t

Compute shelf prices: $\tilde{b}_p \leftarrow b_p(1 - d_{t,p})$ for all p
Compute self-elasticity multiplier: $\mu \leftarrow \frac{1}{P}\sum_p (1 - d_{t,p})^{\varepsilon}$
Draw arrivals: $N_t \sim \text{Poisson}(\lambda \cdot m_{w(t)}) \cdot \mu$
Generate N_t customers with segments and WTP vectors
Simulate purchase decisions $\rightarrow$ base demand $\mathbf{q}_t^{\text{base}}$
Apply cross-elasticity: $q_{t,p} \leftarrow \text{clip}\big(q_{t,p}^{\text{base}} - \sum_j E_{pj} d_j q_{t,p}^{\text{base}},\ 0,\ i_{t,p}\big)$
Update inventory: $i_{t+1,p} \leftarrow i_{t,p} - q_{t,p}$
Compute discount cost: $\Delta_t \leftarrow \sum_p b_p \cdot d_{t,p} \cdot q_{t,p}$
Update budget: $B_{t+1} \leftarrow B_t - \Delta_t$
Update cumulative cost: $c_{t+1,p} \leftarrow c_{t,p} + b_p \cdot d_{t,p} \cdot q_{t,p}$
Decrement time: $T_{t+1} \leftarrow T_t - 1$
return $(\mathbf{i}_{t+1}, B_{t+1}, T_{t+1}, \mathbf{c}_{t+1}, \mathbf{q}_t)$

5.5 Reward Function and Budget Pacing

The reward function balances three objectives:

$$\boxed{R_t = \underbrace{M_t}_{\text{margin}} + \underbrace{\beta \sum_p q_{t,p}}_{\text{clearance bonus}} - \underbrace{\gamma\big|\Delta_t - \Delta^*\big|}_{\text{pacing penalty}} + \underbrace{\Phi_t}_{\text{budget penalty}}} \tag{21}$$

where:

- $M_t = \sum_p (\tilde{b}_p - c_p) q_{t,p}$ is the total daily margin.
- $\beta = 1.0$ is the per-unit clearance bonus, incentivizing inventory reduction.
- $\Delta^* = B_0/H$ is the target daily discount spend for uniform budget pacing, where B_0 is the initial budget and H is the horizon.
- $\gamma = 0.5$ is the pacing penalty coefficient.
- Φ_t is the budget overrun penalty:

$$\Phi_t = \begin{cases} -500 & \text{if } B_t < 0 \text{ and } T_t > 0 \quad \text{(early exhaustion)}, \\ 0 & \text{otherwise.} \end{cases} \tag{22}$$

Budget Pacing Mechanism. The pacing penalty term $\gamma|\Delta_t - \Delta^*|$ implements a **soft constraint** that encourages the agent to spend its discount budget at a uniform rate of $\Delta^* = B_0/H$ per day.

- If the agent overspends early (high Δ_t), the penalty increases, discouraging aggressive discounting.
- If the agent underspends (low Δ_t), the penalty also increases, preventing the agent from hoarding budget.
- The hard penalty $\Phi_t = -500$ provides a **safety net**: any policy that exhausts the budget before the markdown period ends receives a catastrophic negative reward, strongly discouraging budget overrun.

The combination of shaped pacing penalty and terminal overrun penalty creates a dual mechanism: gradient signal for smooth learning (shaped reward) and a hard boundary for safety (terminal penalty).

6 Product Catalog

The default catalog consists of 15 products across 5 categories:

Table 9: Product catalog with pricing and inventory parameters.

ID	Product Name	Category	Base Price	Unit Cost	Margin %	Init. Inv.
0	Organic Milk 1L	dairy	\$4.50	\$2.20	51%	600
1	Greek Yogurt 500g	dairy	\$5.00	\$2.50	50%	550
2	Cheddar Cheese 200g	dairy	\$6.00	\$3.00	50%	450
3	Sourdough Bread	bakery	\$5.50	\$2.00	64%	650
4	Croissant 4-pack	bakery	\$4.00	\$1.50	63%	600
5	Whole Wheat Wrap 6pk	bakery	\$3.50	\$1.20	66%	550
6	Atlantic Salmon 300g	protein	\$12.00	\$7.00	42%	300
7	Chicken Breast 500g	protein	\$8.00	\$4.50	44%	450
8	Plant-Based Burger 2pk	protein	\$9.50	\$5.00	47%	350
9	Cabernet Sauvignon	beverages	\$15.00	\$8.00	47%	250
10	Craft IPA 6-pack	beverages	\$12.00	\$6.50	46%	300
11	Sparkling Water 12pk	beverages	\$6.00	\$2.50	58%	650
12	Dark Chocolate Bar	snacks	\$4.00	\$1.80	55%	750
13	Trail Mix 400g	snacks	\$7.00	\$3.50	50%	500
14	Protein Bar 6-pack	snacks	\$8.50	\$4.00	53%	420

Total initial inventory: 7,370 units. Total markdown budget: \$9,000.

7 Cross-Elasticity Structure

The cross-elasticity matrix encodes two types of product interactions:

Substitutes ($E_{ij} = +0.15$). Products within the same category are substitutes. Discounting one product in a category draws demand away from other products in that category. There are 30 such substitute pairs across the 5 categories.

Complements ($E_{ij} = -0.075$). Two category pairs are modeled as complementary:

- **Dairy–Bakery**: Bread and cheese/milk are consumed together. Discounting bread boosts dairy sales.
- **Snacks–Beverages**: Discounting snacks boosts beverage purchases and vice versa.

There are 36 complement pair entries in the matrix.

8 Implementation Details

8.1 Class Structure

Listing 1: Core class interface (simplified).

```
class SimulatorConfig:
    products: List[ProductSpec]
    n_products: int
    allowed_discounts: List[float]
    cross_elasticity_matrix: np.ndarray
    total_markdown_budget: float
```

```
    markdown_horizon: int

class RetailSimulator:
    def __init__(config: SimulatorConfig)
    def reset() -> None
    def step(discounts: np.ndarray) -> StepResult
    @property done -> bool
    @property time_remaining -> int

class MarkdownPricingEnv(gym.Env):
    observation_space: spaces.Box  # (70,)
    action_space: spaces.MultiDiscrete  # [5]*15
    def reset() -> (obs, info)
    def step(action) -> (obs, reward, term, trunc, info)

class DataGenerator:
    def generate(policy: str) -> dict[DataFrames]
```

8.2 Observation Normalization

All state components are normalized to approximately $[0, 1]$:

- Inventory is divided by initial inventory.
- Demand is divided by initial inventory.
- Cumulative costs are divided by total budget.
- Budget remaining and time remaining are expressed as fractions.
- Day-of-week is one-hot encoded.

8.3 Reproducibility

The simulator uses NumPy's `default_rng` with configurable seeds, ensuring full reproducibility of episodes and generated datasets.

9 Verification Results

We ran a verification suite to validate all components:

9.1 Core Engine Test

A single-step test with uniform 10% discounts verified correct financial mechanics: discounted shelf prices, margin calculations, inventory decrements, and budget depletion all matched analytical expectations.

9.2 Environment Test

A full 13-step episode (91 days with weekly decisions) with random masked actions:

- Observation vector shape: (70,) matching $4 \times 15 + 2 + 7 + 1$.
- Action space: `MultiDiscrete([5, 5, ..., 5])` with 15 products.
- Action masking correctly enforces zero-discount for depleted products.

- Episode length: 13 MDP steps (13 weekly decisions over 91 days).
- Sticky pricing: each action is applied for 7 consecutive simulation days.

9.3 Demand Regime Verification

We verified that the parameter configuration ($\lambda = 80$, total inventory 7,370, budget \$9,000, 91-day horizon with seasonal events) creates a non-trivial optimization landscape:

- **Zero discount**: 4,760 of 7,370 units sold (64.6% clearance), demonstrating that organic demand is insufficient to clear inventory even over the extended horizon.
- **Heuristic policy**: 7,358 of 7,370 units sold (99.8% clearance), showing that strategic discounts are necessary and effective for full clearance.

The seasonal event calendar introduces an additional challenge: the January Clearance period ($e_t = 0.7$) depresses demand in the final weeks, creating urgency to clear stock during the holiday peaks.

9.4 Promotional Attention Verification

The promotional attention mechanism (Section 3) was validated by comparing purchase behavior of 100 customers with no discount versus 30% discount on a single product, averaged over 50 trials:

- **Discounted product**: 3.1 $\rightarrow$ 33.1 units (10.6$\times$ lift).
- **Same-category substitutes**: -1.1 units (mild cannibalization).
- **Total catalog sales**: 65.8 $\rightarrow$ 82.9 units (+26% lift).

9.5 Seasonality Verification

Day-of-week demand patterns under zero-discount policy (30 episodes):

Table 10: Realized demand by day of week vs. configured arrival multipliers.

Day	**Avg Units Sold**	**Configured m_w**	**Realized Ratio**
Mon	40.9	0.80	0.79
Tue	43.4	0.85	0.84
Wed	46.9	0.90	0.91
Thu	51.6	1.00	1.00
Fri	59.2	1.15	1.15
Sat	66.7	1.30	1.29
Sun	61.8	1.20	1.20

Realized demand ratios closely match the configured multipliers, confirming correct seasonality implementation.

10 Usage Guide

10.1 Generating Offline Data

Listing 2: Generating CSV datasets for offline pre-training.

```python
from simulator import DataGenerator, SimulatorConfig

config = SimulatorConfig(seed=42)
gen = DataGenerator(config, output_dir="outputs")
data = gen.generate(policy="heuristic")
# Outputs: product_metadata.csv,
#          daily_state_transitions.csv,
#          transaction_log.csv
```

10.2 Training an RL Agent

Listing 3: Using the Gymnasium environment for RL training.

```python
from simulator import MarkdownPricingEnv, SimulatorConfig

config = SimulatorConfig(seed=42)
env = MarkdownPricingEnv(config)

obs, info = env.reset()
for _ in range(config.n_decisions):  # 13 weekly steps
    mask = info["action_mask"]
    action = my_policy(obs, mask)  # Your RL policy
    obs, reward, done, trunc, info = env.step(action)
    if done:
        break
```

11 RL Policy Training

We train a Soft Actor-Critic (SAC) agent on the simulator environment and compare against baseline policies.

11.1 Algorithm

11.1.1 Soft Actor-Critic (SAC)

11.1.2 Soft Actor-Critic (SAC)

SAC requires a continuous action space. We wrap the environment with a `ContinuousActionWrapper` that maps continuous actions $a \in [0,1]^P$ to nearest discrete discount tiers:

$$d_p = \text{argmin}_{d \in A_{\text{allowed}}} \left| a_p \cdot d_{\max} - d \right|, \qquad d_{\max} = 0.5. \tag{23}$$

Table 11: SAC hyperparameters.

Parameter	**Value**
Learning rate	1×10^{-4}
Replay buffer size	100,000
Learning starts	1,000
Batch size	256
Target smoothing (τ)	0.005
Discount (γ)	0.995
Entropy coefficient	auto (learned)
Network architecture	[256, 128]
Total timesteps	200,000

Hyperparameters.

11.2 Baseline Policies

Random Policy. Uniformly samples a discount tier from A_{allowed} for each product at each step, subject to inventory masking.

Heuristic Policy. Computes a pressure index per product:

$$\text{pressure}_p = 0.5 \cdot \frac{t}{H} + 0.5 \cdot \frac{i_{t,p}}{i_{0,p}}, \tag{24}$$

mapping the result to a discount tier with a budget guard that caps discounting when the remaining budget fraction $B_t/B_0 < 0.2$.

11.3 Training Convergence

SAC was trained for 200,000 timesteps (≈15,385 episodes of 13 steps each). The running average reward stabilized at ≈26,000, with low variance, indicating convergent and reliable policy learning. SAC's off-policy replay buffer and learned entropy coefficient enable efficient exploration of the 13-step weekly decision space.

11.4 Evaluation Results

Each policy was evaluated over the 91-day (13-week) horizon:

Table 12: Policy comparison: evaluation metrics over the 91-day markdown period.

Metric	**Zero Disc.**	**Random**	**Heuristic**	**SAC**
Total reward	17,953	−27,975	22,080	**26,171**
Total revenue	\$35,457	\$24,750	\$40,069	**\$44,994**
Total margin	\$17,693	\$7,281	\$16,972	**\$21,873**
Discount cost	\$0	\$17,469	\$7,749	**\$2,868**
Units cleared	4,760	7,367	7,358	**7,364**
Clearance rate	64.6%	99.9%	99.8%	**99.9%**
Budget remaining	\$9,000	—	\$1,251	**\$6,132**

11.5 Analysis

Key Findings:

1. **SAC dominates on all metrics.** It achieves the highest margin ($21,873), lowest discount spend ($2,868), near-complete clearance (7,364 of 7,370 = 99.9%), and the highest reward (26,171). This corresponds to a **29% margin improvement** over the heuristic while using **63% less** discount budget.

2. **Zero-discount baseline validates the optimization landscape.** Without any discounting, only 64.6% of inventory is cleared (4,760 of 7,370 units), leaving over 2,600 units unsold. This confirms that the demand-supply balance ($\lambda = 80$, inventory 7,370, 91-day horizon) makes discounting genuinely necessary for inventory clearance.

3. **SAC learns strategic discount deployment across seasonal events.** Trajectory analysis reveals that SAC applies moderate discounts early (weeks 1–4, $394–437/week) to build steady clearance, then pulls back sharply during high-demand holiday weeks (Cyber Week and post-Christmas) where organic demand is sufficient. In the final weeks (January Clearance, $e_t = 0.7$), SAC applies targeted discounts to clear the remaining stock. Total budget utilization is only 32% ($2,868 of $9,000).

4. **Heuristic is a strong contender but overspends.** The pressure-based heuristic achieves $16,972 margin with 99.8% clearance. However, it spends $7,749 on discounts—2.7× more than SAC—because it reacts to inventory pressure mechanically rather than anticipating demand surges from seasonal events.

5. **Random policy is catastrophic.** Random discounting exhausts the $9,000 budget rapidly, incurring continuous budget overrun penalties (−500 per step) for many remaining weeks. Despite achieving 99.9% clearance, the massive discount expenditure ($17,469) destroys all margin.

6. **Seasonal events create strategic opportunities.** The SAC agent learns to exploit Black Friday/Cyber Week demand surges (2.5× and 1.4× multipliers) by applying lower discounts during these events—organic demand is already elevated—and saving discount budget for the January Clearance period when demand drops to 0.7×.

Detailed SAC Trajectory (13-Week). A representative 91-day SAC trajectory (seed = 42) shows:

- Revenue: $44,994, Margin: $21,873, Discount cost: $2,868.
- Units cleared: 7,364 of 7,370 (99.9%).
- Budget remaining: $6,132 of $9,000 (used only 32% of available budget).
- Inventory depletion is nearly monotonic: $7{,}370 \to 6{,}733 \to \cdots \to 867 \to 356 \to 6$.
- Holiday weeks show adaptive behavior: during Cyber Week (day 34), SAC generates $4,693 revenue with only $253 discount cost, leveraging the 1.4× demand multiplier. During January Clearance (days 76–90), SAC applies targeted discounts ($50–121/week) to clear the final 867 units.

12 Synthetic Data Generation (Transaction Log Role)

The three CSV outputs serve distinct roles:

- `daily_state_transitions.csv`: Contains the MDP tuples (s_t, a_t, r_t, s_{t+1}) used for offline batch RL or behavioral cloning.
- `product_metadata.csv`: Static catalog reference for feature engineering.
- `transaction_log.csv`: A **diagnostic artifact** recording individual customer-level purchases (WTP, surplus, segment). This log is *not* consumed by the RL agent—it provides visibility into the hidden dynamics for:
  1. Validating economic plausibility of the simulator (e.g., verifying WTP distributions, segment purchase rates).
  2. Building auxiliary demand forecasting models.
  3. Conducting counterfactual analysis on customer behavior under different pricing regimes.

13 Conclusion

This report presents a complete, verified simulator and RL training pipeline for dynamic markdown pricing. The system models realistic retail complexities including customer heterogeneity, price elasticity, cross-product interactions, promotional attention effects, seasonal event calendars (Black Friday through January Clearance), weekly sticky pricing decisions, inventory constraints, and budget pacing. The Gymnasium-compatible interface with discrete action tiers and action masking enables direct integration with standard RL libraries.

The calibrated demand regime ($\lambda = 80$ daily arrivals, 7,370 units of inventory, \$9,000 markdown budget, 91-day horizon with 8 seasonal events) creates a non-trivial optimization problem where zero-discount clears only 64.6% of inventory. The promotional attention mechanism ensures that discounts create genuine demand lift (10.6× for a 30% discount), and the seasonal event calendar introduces non-stationary demand patterns that the agent must anticipate and exploit.

Training SAC on this environment yields a policy that achieves \$21,873 in margin—29% above the heuristic—while using only 32% of the available discount budget and clearing 99.9% of inventory. The learned policy makes 13 weekly pricing decisions, strategically reducing discounts during high-demand holiday events and targeting remaining stock during the January Clearance period.

Future extensions include: (i) competitor pricing signals, (ii) multi-store coordination, (iii) sim-to-real transfer using offline RL pre-training on the generated CSV datasets, and (iv) incorporating demand forecasting models to further improve policy robustness.
